Objective: Despite reliable evidence of abnormal scapular motions increases, there is not yet sufficient evidence of abnormal humeral translations. This study aims to analyze the motion of the humeral head toward the scapula when the shoulder is actively abducted using the C-arm.

Design: A case report.

Methods: The participant was a healthy man without any limitation and pain during shoulder movement. The participant's shoulder was abducted; this movement in the frontal plane was measured using a C-arm (anterior-posterior view) and was analyzed with computer-aided design. The starting posture was 15°, and as the participant abducted his shoulder measurements were taken and analyzed at 30°, 60°, 90°, 120°, 150°, and ending at 165°. A line was drawn perpendicularly to the line connecting the humeral head axis to the glenoid, and another line was drawn perpendicularly to the line connecting the scapular axis to the glenoid. The distance between the two lines measured is defined as the e value.

Results: At the starting posture (15°), the central axis of the humeral head was located 1.92 mm inferior to the central axis of the scapula. The humeral head was superiorly translated from the starting posture to 120°, and then, showed an inferior translation to the ending posture (165°).

Conclusions: The results of this study showed that the humeral head moved upward from the starting posture (15°) up to 120° indicating, superior translation, and it moved downward when the posture was past 120°, indicating inferior translation.

Key Words: C-arm, Kinematic analysis, Shoulder abduction

Introduction

Generally, 34% of the population complains of shoulder pain more than once in a lifetime [1], and its prevalence is 20.9%, placing it as the second common impairment in the musculoskeletal system [2]. In addition, shoulder dysfunction is continuous and repetitive [3]. An important key to shoulder function is the rotator cuff [4]. In addition, for the stabilization of the humeral head toward the glenoid during shoulder abduction, normal function of the rotator cuff is necessary [5,6]. Rotator cuff injury affects 30% to 40% of

the population over the age of 60 years and has a significant impact on medical expenses [7]. Repairs for rotator cuff injury continue to increase, and physical therapy for this is important [8,9]. In addition, assessment of pain after the repair using a pain scale, such as the visual analog scale and range of motion (ROM) is important [10]. Self-exercise, joint mobilization and continuous passive movement are often used to enhance ROM [11].

For joint mobilization, physical therapists often use the concepts of Kaltenborn, Maitland, and Mulligan [12]. Kaltenborn and Evjenth [13] proposed joint mobilization ac-

cording to the convex-concave rule on glide. The convex-concave rule is considered a critical theory in physical therapists' treatment decision-making [14]. The humeral head (convex) glides in the opposite direction when it moves to the glenoid (concave). This refers to the inferior glide of the humeral head in shoulder abduction [15]. Joint mobilization is an approach that makes a motion in the reduced direction to restore the normal movement, and the direction of the glide is determined considering the shape of the joint surface [15]. However, a recent study raises a question about this principle [16]. A previous study of a cadaver noted that 40% of the fibular joint surface of tibiofibular joints was plane; 57% convex and concave; and 3% convex [17]. This study shows the difficulty in the application of the convex-concave rule according to the joint surface [16]. In addition, a study of the joint translation noted that superior translation of the humeral head occurred (average 2 mm) in shoulder abduction [18]. Nishinaka *et al.* [19] reported that in shoulder abduction from 0° to 80°, the humeral head moved upward of approximately 1.7 mm and that from 80° to 150°, the humeral head moved upward of less than 1 mm. In addition, Graichen *et al.* [20] reported that in shoulder abduction from 30° to 120°, there was a superior translation of the humeral head. In shoulder abduction from 120° to 150°, there was an inferior translation of the humeral head.

In addition, a dispute over joint mobilization based on the controversial convex-concave rule is also in progress [16]. Kaltenborn's convex-concave rule is a familiar concept in joint treatment techniques and arthrokinematics. However, the weighting of the evidence according to the Elwood [21] classification and the agency for health care policy and research [22] classification guidelines indicated that the evidence was weak and limited. The indirect method, using Kaltenborn's convex-concave rule as applied to the glenohumeral joint, may need to be reconsidered [15].

Despite reliable evidence of abnormal scapular motions increases, there is not yet sufficient evidence of abnormal humeral translations [23-25]. Shoulder kinematics was analyzed using standard radiographs [4,5,26-28], magnetic resonance imaging (MRI) [29-32], ultrasound [33] and computed tomography (CT) [34]. Of the researchers, Poppen and Walker [5] defined the axis of the humerus and scapula using standard radiographs and analyzed the motion, accordingly. In most previous studies, images were shot in static positions, and dynamic glenohumeral arthrokinematics was not described [35]. In addition, because the two-dimensional (2D) radiographic approach was used in

both of these studies, descriptions of humeral head translations were limited to static measures in the superior-inferior direction and were subject to possible projection errors [36]. It is difficult to measure dynamic humeral head translation, but the results of a 3D analysis during the clinical shoulder motion are beginning to be reported [19,37,38]. It seems that treatment and rehabilitation of shoulder injuries will be enhanced with better knowledge of glenohumeral mechanics during dynamic activities in healthy and pathologic joints [19]. The number of studies projecting the body's motion and analyzing joint motion using the C-arm (GE OEC 9800 plus; GE OEC Medical Systems Inc., Salt Lake City, UT, USA, 2012) that can move and shoot X-ray images continue to increase [39].

Thus, through this study, we visually recorded the movement of the humerus toward the scapula when the shoulder is abducted dynamically and consecutively. This study aims to analyze the motion of the humeral head toward the scapula when the shoulder is abducted actively using the C-arm.

Methods

Subjects

This study recruited one healthy man through the bulletin board in Kyungnam University. The participant's characteristics were as follows: age, 28 years; height, 183 cm; and weight, 85 kg. The participant who did not have any pain in the shoulder joint, did not have a history of any injury on the muscles around the joint and the skeleton, and could perform shoulder abduction within normal ROM was selected. Persons who had congenital disorders in the shoulder joint or surrounding muscles and skeleton, those who had side effects (vomiting, diarrhea or dizziness) in an X-ray exam, those who had adhesive capsulitis, degenerative arthritis and active inflammatory disease were excluded. The participant joined voluntarily and signed an agreement to participate. This study was conducted after the approval of Kyungnam University Ethics Commission (IRB No. 1040460-A-2016-011).

Measure

The C-arm used in this study was 1,024×1,024 pixels. The image processing speed was 16-bit, which can enlarge images from 9 to 12 inches. The measurement was taken in the anterior-posterior direction. The participant was asked to sit on a chair in an anatomical position, rotating 30° from the X-ray beam (30° from the frontal plane). The 30° rotation

was to make the scapular plane and X-ray beam on a straight line. The shoulder was located at least within 2 cm from an image intensifier to minimize distortion. In order to minimize exposure to the X-ray, the participant was asked to wear a lead dress on the parts other than those used for the experiment. The height of the C-arm was adjusted so that the entire ROM of the proximal axis of the shoulder joint and humerus was displayed. Then, the participant raised the arm sideways. A radiologist with five years of clinical experience had made these measurements. Beginning from the starting posture (15°), measurements were taken at intervals of 30° , 60° , 90° , 120° , 150° , and the ending posture (165°) as the participant abducted the shoulder. A line was drawn perpendicularly to the line connecting the humeral head axis to the glenoid, and another line was drawn perpendicularly to the line connecting the scapular axis to the glenoid. The distance measured between the two lines was defined as the e value. The measurements were taken dynamically and consecutively, and the results were saved in video and picture files, which could be observed later. The picture files were captured (135°), and a professional designer took these and conducted computer-aided design (CAD) work.

The standard definitions of the humeral translation and the angle of the humerus were based on Poppen and Walker [5] (Figure 1). In order to show anatomical characteristics, AutoCAD software (Autodesk Inc., San Rafael, CA, USA, 2014) was used, and an image-transforming operation was conducted by a designer with an 8-year experience in CAD. The designer was not aware of the contents of the study. The glenoid was described by drawing lines on the top and bottom edges of the glenoid, and the center was defined as the axis of the scapula (Os) (Figure 1; ①). A circle was drawn around the humeral head, and the center was defined as the axis of the humeral head (Oh) (Figure 1; ②) [5]. Lines were drawn, respectively, perpendicular to the lines from the Os and Oh to the glenoid. The distance measured between the two lines was defined as the e value (Figure 1; ③) [5]. Variable e can be expressed by the glide of the humeral head toward the glenoid or the distance of the translations. At the center of the scapula, the center of the humeral head can move upward or downward [4]. Using this figure, the translations of the humeral head toward the glenoid were analyzed by the angle.

Results

The starting posture (15°) entailed having the participant

Figure 1. Radiographic analysis. a: axis of the scapula, b: axis of the humeral head (Oh), c: the e value.

sit comfortably in a chair in an anatomical position. At this angle, the central axis of the humeral head was located to be 1.92 mm lower than the central axis of the scapula (inferior). When the shoulder was abducted to 30° , the e value was $+0.02$, and the humeral head was translated superiorly of 1.94 mm from the starting posture. When the shoulder was abducted from 30° to 60° , the e value was $+1.06$, and the humeral head was translated superiorly of 1.04 mm. When the shoulder was abducted from 60° to 90° , the e value was $+1.40$, and the humeral head was translated superiorly of 0.34 mm. When the shoulder was abducted from 90° to 120° , the e value was $+1.87$, and there was a superior translation of 0.47 mm of the humeral head. When the shoulder was abducted from 120° to 150° , the e value was $+0.30$, and the humeral head was inferiorly translated of 1.57 mm. When the shoulder was abducted from 150° to 165° , the e value was $+0.20$, and the humeral head was inferiorly translated of 0.10 mm. From the starting angle to 120° , the humeral head was superiorly translated relative to the scapula and then was translated inferiorly (Table 1).

Discussion

The motion of the humeral head at the shoulder joint surface was studied for the first time by Poppen and Walker [5]. This study defined the axis of the humeral head and the axis of the scapula, and it conducted static experimental research

Table 1. Change in e value by angle

Angle	e value (mm)	Translation (mm)
Start position (15°)	-1.92	-
30°	+0.02	1.94
60°	+1.06	1.04
90°	+1.40	0.34
120°	+1.87	0.47
150°	+0.30	1.57
End position (165°)	+0.20	0.10

using X-ray [5]. Later studies, too, have depended on cadaveric simulations [18], 2D imaging [5], static 3D imaging [40-42] and conventional motion measurement systems [36]. Cadaveric experiments can provide accurate measures of joint position or motion, but are unable to duplicate the complex motions or forces associated with in vivo conditions [43]. The shoulder joint was experimented in 3D using MRI [41], CT [40], and biplane radiography [42], but currently, these technologies are limited to static analyses.

This study conducted serial radiography in shoulder abduction using the C-arm that can conduct dynamic experiments, and followed the definitions of the axis of the humeral head and the axis of the scapula by Poppen and Walker [5]. In addition, the digital image was analyzed using CAD.

Bey *et al.* [43] found that when the shoulder was abducted, the humeral head was translated superiorly then inferiorly in both the repaired rotator cuff and the contralateral shoulder. The differences in the previously mentioned study is that it was conducted with a patient after supraspinatus surgery and static 3D imaging and biplane radiography were used; the patient was also holding a weight as the experiment was conducted. These findings were the same as the result of Graichen *et al.* [41] which was the inferior translation of the humeral head from 30° to 150°. However, Graichen *et al.* [41] measured passive ROM, which is different from the measurement of active ROM in this study. Boyer *et al.* [37] reported on the superior translation of the humeral head from 0° to 45° and its inferior translation from 45° to 90° in a 3D evaluation of the humeral head motion.

According to Poppen and Walker [5] the humeral head was superiorly translated as the shoulder was abducted in both groups with and without a problem in the shoulder. A later study by Deutsch *et al.* [4] revealed significant findings of the superior translation of the humeral head in impingement syndrome.

In this study, the healthy participant actively abducted the shoulder, which was measured at every 30°. It was found

that the humeral head moved upward from the starting posture (15°) up to 120°, indicating superior translation, and it moved downward when the posture was past 120°, indicating inferior translation. A previous study showed the same result of the humeral head moving upward from 30° to 120° and moving downward from 120° to 150° during shoulder abduction [20].

A study found that during active shoulder abduction, the superior translation of the humeral head from the inferior to the center of the glenoid is an average of 1.7 mm [19]. Another study found that the superior translation of the humeral head increases regardless of the angle [35]. Both studies investigated healthy participants without any shoulder disease. Chen *et al.* [26] also, investigated healthy participants. In the group before exercise, the superior translation of the humeral head moved in shoulder abduction from 0° to 135°, but it was not significant. In the group after the exercise, the superior translation of the humeral head was discovered (2.8 mm) in shoulder abduction from 0° to 90°, and inferior translation was discovered (0.3 mm) from 90° to 135° [26]. A later study also found that the superior translation of the humeral head was discovered (average, 0.79 mm) in shoulder abduction after the fatigue of the supraspinatus, infraspinatus, and teres minor muscles [35].

According to Schomacher [16] the reasoning model of the convex-concave rule is that the axis of motion should be considered stationary for simplification; however, it was reported that the rolling component in human joints shifts the axis. This report refutes the problem of the first approach to the convex-concave rule, as well as the problem in the setting of the direction of the joint motion. In addition, he argued that it is important to find the actual motion limitation and execute the joint mobilization rather than deciding the joint mobilization only from a pathological perspective [16]. In other words, if there is a limitation in shoulder abduction, it is important to find and execute the actual limitation direction of the glide, rather than executing the inferior glide of the humeral head without a test. Lazennec *et al.* [17] found that 55% of the tibial joint surface was plane; 40%, convex; and 5%, concave. This is an example that demonstrates how difficult it is to apply the convex-concave rule according to the surface of the joint [16]. Studies supporting this challenge have also concluded that superior translation of the humeral head occurs in shoulder abduction.

A limitation of this study is that it is a pilot study in which only one young, healthy man participated; therefore, it is difficult to generalize the results to other age groups, women,

or people with shoulder dysfunction. Another limitation is that it did not measure direct humeral head translation within the joint, so it is difficult to understand the exact data values. It would be necessary to further conduct the study with more participants and investigate the actual motion by shooting with the scale, which is the basis in shooting with a C-arm in the future. We believe that for shoulder kinematics, dynamic C-arm measurement and analysis can provide important information to increase the understanding of shoulder function. In addition, it is judged that this information will lead to a better strategy for rehabilitation.
