Department of Physical Therapy, Hoseo University, Asan, Republic of Korea

Objective: This study aimed to investigate the effect of different-sized airways of the inspiratory muscle trainer (IMT) on maximal inspiratory pressure (MIP) and the rating of perceived exertion, as measured by the modified Borg scale (m-Borg).

Design: Cross-sectional study.

Methods: Twenty healthy subjects (10 men, 10 women) volunteered for the study. The spirometry was used to measure MIP. The trial order of the three spirometry conditions was chosen randomly. After measuring the MIP and before taking the final break, each of the conditions were immediately measured using the m-Borg. All subjects used the IMT with an airway diameter of 5-, 6-, and 7-mm.

Results: The MIP significantly decreased with the decreasing airway diameter of the IMT ($p < 0.001$), and the differences in all three conditions (7- and 6-mm, 6- and 5-mm, and 7- and 5-mm airways) were significant ($p < 0.05$). The RPE significantly increased with the decreasing airway diameter of the IMT ($p < 0.001$), and the differences in all three conditions (7- and 6-mm, 6- and 5-mm, and 7- and 5-mm airways) were significant ($p < 0.05$).

Conclusions: Decreasing the airway diameter of the IMT decreased the MIP and increased the m-Borg. In regards to physical exercise within the clinical setting, the m-Borg could be a useful as a prior monitoring method to prevent dyspnea for patients with narrowed airways (blocked with secretion or sputum in pulmonary disease) and the different-sized airways of the IMT could be applied as a useful tool to improve MIP for prevention of pulmonary disease.

Key Words: Airway resistance, Maximal respiratory pressures, Pulmonary ventilation

Introduction

The rapid industrialization of the Korean society and aging of the population has elevated the incidence of respiratory diseases and its effects on the public health [1]. Pulmonary rehabilitation is a multidisciplinary field, and included in the multiple specialists involved, the role of physical therapists is critical for improving subjects' mobility and physical strength [2].

Physical therapists are healthcare professionals who enable individuals to demonstrate their maximum physical ability by assessing their physical functions and providing

individualized interventions for their problems. A physical therapist's greatest interest is on how well the subject moves, how well the therapist is able to help the patient move, and ultimately in how well the subject can execute daily living activities through motor learning [3].

If a subject encounters breathing difficulties during pulmonary rehabilitation because the physical therapist did not grasp the level of resistance and perceived exertion felt by the patient, the physical therapist would have difficulty forming a good rapport with the patient. To understand these factors, it would be useful to examine the load on the inspiratory muscle and perceived exertion at inspiration amid

increased airway resistance caused by airway secretions [4]. However, there has been no report on the effects of airflow resistance caused by changes of airway diameter during inspiration on maximal inspiratory pressure (MIP) and rating of perceived exertion [5].

Therefore, this study aims to investigate the effects of different-sized airways of the inspiratory muscle trainer (IMT) on MIP and the rating of perceived exertion in healthy adults, as measured by the modified Borg scale (m-Borg). Ultimately, this study attempts to understand the position of individuals with respiratory disease undergoing pulmonary rehabilitation and to provide reference data pertaining to the setting of appropriate exercise intensity in consideration of perceived exertion for rehabilitative exercise therapy. This study hypothesized that the “MIP and m-Borg will change in relation to the changes of the airway diameter of the IMT.”

Methods

At Hoseo University (located in Asan, Chungnam Province), 20 healthy young people were recruited through a public announcement and voluntarily enrolled in the study after being adequately informed of the details of the study. This study was approved by the Institutional Review Board at Hoseo University (IRB No. 104123-170904-HR-063-02). The participants' general characteristics are shown in Table 1.

To measure MIP, the spirometer, Pony FX MIP/MEP (Cosmed Srl, Rome, Italy) [6], and a POWER breathe Try Safe Filter mouthpiece that included a sterilized gauze were used. The chosen IMT (Inspiratory Muscle Trainer; Smith

Medical Inc., Minneapolis, MN, USA) had diameter options of 7 mm, 6 mm, and 5 mm, and the diameter was adjusted using the resistive tips (Figure 1) [7]. MIP was measured at each diameter, and perceived exertion was measured using the m-Borg [8].

The participants wore comfortable clothing without outerwear and sat on a chair in an indoor laboratory with a temperature of 24°C and were given an explanation about the process of measuring MIP. After placing the nose clip, the participants bit on the mouthpiece and familiarized themselves with the process by following the instructions of, “take a deep breath and breath out as strong as possible for six seconds” (Figure 2) [9]. After the familiarization process, the participants were provided with a three-minute break. MIP was measured three times, after which MIP was measured. A one-minute break was taken between measurements so participants could recover to a normal breathing pattern. The median value was used for the data.

The resistance tip and mouthpiece containing a sterile gauze was used to measure MIP. MIP was measured three times by adjusting the diameter of the trainer by inserting a tip on the corresponding diameter (7 mm, 6 mm, and 5 mm) between the mouthpiece and inspiratory muscle measurement device. The order of the three conditions was chosen randomly, and the participants rested for at least one minute between each measurement to recover normal breathing. After measuring the MIP and before taking the final break, the m-Borg in each of the conditions was immediately measured.

The independent variable of this study was airway resistance, and the dependent variables were MIP and m-Borg.

Table 1. Characteristics of subjects (N=20)

Characteristic	Value
Sex	
Male	10 (50)
Female	10 (50)
Physical characteristic	
Age (y)	20.9 (1.1)
Height (cm)	168.0 (7.9)
Weight (kg)	65.8 (9.2)
Body mass index (kg/m ²)	23.3 (1.5)
Lung capacity	
Forced vital capacity (L)	4.6 (0.7)
Forced expiratory volume in 1 second (L)	3.9 (0.6)
Maximal inspiratory pressure (cm/H ₂ O)	93.7 (25.0)

Values are presented as n (%) or mean (SD).

BMI: body mass index, FVC: forced vital capacity, FEV1: Forced expiratory volume in 1 second, MIP: maximal inspiratory pressure.

Figure 1. Spirometer, Pony FX MIP/MEP (Cosmed Srl, Rome, Italy).

The collected data was analyzed using IBM SPSS Statistics ver. 20.0 (IBM Co., Armonk, NY, USA), and statistical significance was tested using repeated measures one-way ANOVA. The Bonferroni's correction was used as the post-hoc test, and statistical significance was set to $\alpha < 0.05$.

Results

Changes of maximal inspiratory pressure

The MIP significantly decreased with the decreasing diameter of the IMT ($p < 0.001$; Table 2), and the Bonferroni's correction revealed that all differences (between 7 mm and 6 mm, between 6 mm and 5 mm, and between 7 mm and 5 mm) were significant ($p < 0.001$).

Changes of perceived exertion

RPE significantly increased with the diameter of the IMT

Figure 2. Maximal inspiratory pressure test in sitting position.

($p < 0.001$; Table 2), and Bonferroni's correction revealed that all differences (between 7 mm and 6 mm, between 6 mm and 5 mm, and between 7 mm and 5 mm) were significant ($p < 0.001$).

Discussion

This study aimed to investigate how MIP and m-Borg are altered in relation to the diameter of the IMT. The results showed that MIP significantly decreased while m-Borg significantly increased with decreasing the airway diameter of the IMT. Based on these results, our hypothesis was supported.

Hulzebos *et al.* [10] suggest that inspiratory muscle training before surgery prevents postoperative pulmonary complications. Dall'Ago *et al.* [11] also insist that inspiratory muscle training increases the MIP to 115%, the peak oxygen uptake to 17%, and the 6-min walk distance. In addition, some authors suggest that it improves blood flow to the resting and exercising limbs after a 4-week program in patients with weakness of inspiratory muscles [12] and so it should be used with a different-sized airway of the IMT as airway resistance of inspiratory muscle training for prevention of pulmonary disease.

On the other hand, airway resistance is the greatest factor in decreased ventilation in patients with chronic obstructive pulmonary disease (COPD) [13]. Airway clearance is also the ultimate goal of pulmonary rehabilitation for COPD patients to reduce airway resistance. In this study, decreasing the diameter of the IMT from 7 to 5 mm decreased the MIP by about 25%. Although the decrease of MIP was not proportionate to the decrease of the airway area, this result shows that reducing the diameter of the IMT increases the difficulty of promoting an adequate influx of air into the alveoli for appropriate ventilation by decreasing the MIP.

Resting alveolar ventilation should be 4 L/min and volume of blood flow through the pulmonary capillaries should

Table 2. Changes of different-sized airways on MIP and m-Borg

(N=20)

Variable	Different-sized airways			F (p)
	7 mm	6 mm	5 mm	
MIP (cm/H ₂ O)	84.34 (21.81) ^a	72.53 (16.46) ^a	63.15 (14.18) ^a	117.403 (<0.001)
m-Borg	0.75 (0.47) ^a	2.30 (0.47) ^a	3.80 (0.70) ^a	147.559 (<0.001)

Values are presented as mean (SD).

MIP: maximal inspiratory pressure, m-Borg: modified Borg scale.

be 5 L/min for proper ventilation [14]. Gas exchange occurs most efficiently at this ratio of ventilation/blood flow (4/5; 0.8) [14]. Patients with COPD are in critical need of fresh air with high oxygen partial pressure because their functional residual capacity is increased from an overexpansion of the lower airway [15].

Elevated airway resistance as a result of the decreased diameter of the IMT adds a greater resistance to the inspiratory muscle that has an insufficient oxygen supply, where fatigue resulting from chronic overuse of the inspiratory muscle adds to the metabolic action, further increasing the ventilation debt and aggravating breathing difficulty [16]. In our study, decreasing the diameter of the IMT significantly lowered MIP and significantly increased m-Borg. This finding suggests that participants are more sensitive to perceived exertion when they must strive to reach the MIP for proper ventilation. In the end, airway clearance must be prioritized to emerge out of the vicious cycle and increase ventilation efficiency to lower perceived exertion (breathing difficulty) [15]. Such effort leads to muscle fatigue over time, and the inspiratory muscles and accessory inspiratory muscles are persistently in a taut state due to overuse [16-18], aggravating postural tension and pain, which intensifies anxiety and fear of breathing difficulty [19]. Therefore, airway clearance should also be the priority for COPD patients to alleviate postural tension and pain. In this context, studying more effective physical therapy interventions to promote airway clearance is crucial for physical therapists.

This study has the following limitations. First, the data were not obtained from patients with a respiratory disease, which limits the generalization of the findings. Patients with respiratory diseases not only have problems such as airway resistance due to a narrowed airway but also have problems involving compliance, such as thoracic cage deformity or compositional changes of respiratory muscle due to chronic fatigue. When reduced compliance is combined with airway resistance, perceived exertion may rise more steeply compared to normal people, even when performing physical activities of the same exercise intensity. In the present study, we could not measure changes of perceived exertion that reflected these problems faced by actual patients with respiratory diseases. Second, inspirational muscle activity was not measured. We did not investigate how increased airway resistance affects muscle activity; thus, we could not present data that would help set appropriate exercise intensity by comparing the muscle use data with our findings. Third, data during physical activity could not be measured, so we do not

know how the increased airway resistance caused by decreasing the diameter of the IMT would have affected perceived exertion in real life activities.

In this study, decreasing the diameter of an IMT decreased MIP and increased m-Borg significantly. Because patients are more sensitive to airway resistance caused by airway narrowing in terms of perceived discomfort or exertion as opposed to developing symptoms of breathing difficulty as a result of elevated burden on the inspiratory muscles, physical therapists should monitor patients using the m-Borg when setting exercise intensity during exercise therapy for pulmonary rehabilitation. Furthermore, the different-sized airway of the IMT also would be applied a useful tool to improve MIP for prevention of pulmonary disease.
